In this demo, we show the new capabilities of the open source P4 compiler called T4P4S-16 [1] (pronounced as “tapas”) developed by our research group at ELTE [4]. Its new features (including the support of P4-16) will be demonstrated through a complex telecom use case, namely a 5G UPF (user plane function). The user plane function handles the critical data plane processing of packets between radio access network consisting of user equipments (UEs) and eNodeBs (eNBs), and the data network (e.g. Internet). The 3GPP specification [2,3] defines a wide set of functionalities associated with the UPF, including access control, GTP-U tunnel encapsulation/decapsulation, bearer lookup, service data flow (SDF) mapping, per-flow QoS, guaranteed bit rate, maximum bit rate, forwarding of packets to/from packet data network, etc.

In this demo, we will demonstrate how a simplified 5G UPF pipeline containing functionalities denoted by bold face and shown in Figure 1a can be implemented in P4-16 (based on v1model). The logical building blocks of the 5G UPF packet processing pipeline are detailed in Figure 1b. The switch program will be generated by the T4P4S-16 compiler with DPDK backend.

We will 1) show how the switch operates with emulated uplink and downlink traffic belonging to end users where the number of users will be varied, 2) introduce the new features of T4P4S-16 and 3) demonstrate the packet processing performance of the generated switch program under realistic emulated traffic with various load levels and table sizes. During the demo, a simple web interface will display the important metrics like the ingress and egress traffic rates (total and per user), number of user, number of CPU cores used, processing delay, etc. in real time. The demo experiments will be carried out in our remote testbed consisting of a switch node, a tester node generating realistic test traffic and two 10Gbps links between them (playing the role of uplink and downlink).
